Lecture 23:

Bagging, Random Forests, & Causal Trees
Big Data and Machine Learning for Applied Economics
Econ 4676

Ignacio Sarmiento-Barbieri

Universidad de los Andes

November 3, 2020

Agenda

- 1 Recap
 - Bagging and Random Forests
 - Comparisons: Lasso, CART, Random Forests
- 2 Causal Trees
 - Causality Review: ATE, CATE, HTE
 - Heterogeneous Treatment Effects
 - Empirical Example
- 3 Review & Next Steps
- 4 Further Readings

CART

- ► Smart way to represent nonlinearities. Most relevant variables on top.
- ► Very easy to communicate.
- Reproduces human decision-making process.
- Trees are intuitive and do OK, but
 - ► They are not very good at prediction
 - ▶ If the structure is linear, CART does not work well.
 - Not very robust

Bagging

- ► We can improve performance a lot using either bootstrap aggregation (bagging), random forests, or boosting.
- ► Bagging & Random Forests:
 - ▶ Repeatedly draw bootstrap samples $(X_i^b, Y_i^b)_{i=1}^N$ from the observed sample.
 - For each bootstrap sample, fit a regression tree $\hat{f}^b(x)$
 - Bagging: full sample
 - ▶ Random Forests: subset of predictors $\sqrt(p)$ (breaks high correlation)
 - Average across bootstrap samples to get the predictor

$$\hat{f}_{bag} = \frac{1}{B} \sum_{b=1}^{B} \hat{f}^{b}(x) \tag{1}$$

- Basically we are smoothing predictions.
- ▶ Idea: the variance of the average is less than that of a single prediction.

4 D > 4 A > 4 E > 4 E > 9 Q P

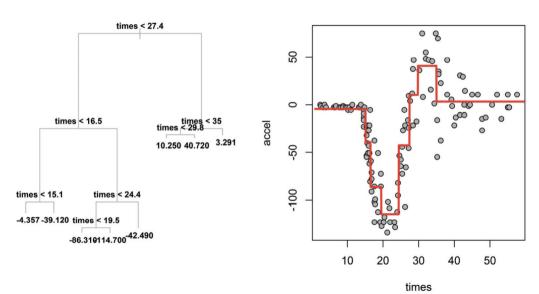

3 / 36

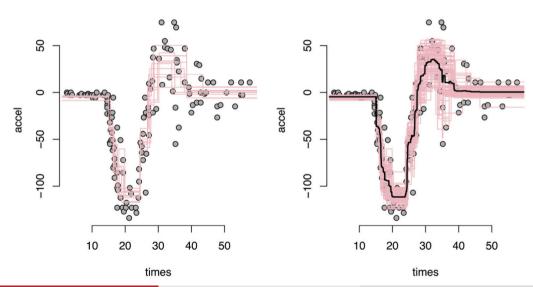

Trees:

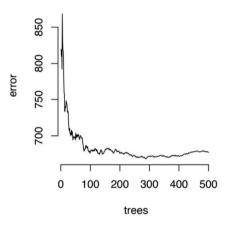

Random Forests:

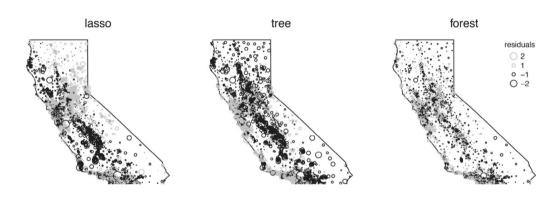

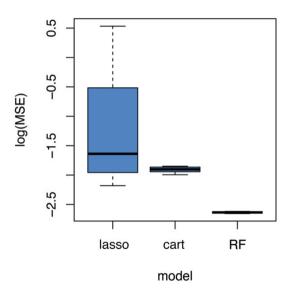

In sample residuals

Out of sample MSE

Treatment Effects

- ▶ We observe a sequence of triples $\{(W_i, Y_i, X_i)\}_i^N$, where
 - $W_i \in \{0,1\}$: is a binary variable indicating whether the individual was treated (1) or not (0)
 - $Y_i^{obs} \in \mathbb{R}$: a real variable indicating the observed outcome for that individual
 - \triangleright X_i : is a p-dimensional vector of observable pre-treatment characteristics
- ▶ Moreover, in the Neyman-Rubin potential-outcomes framework, we will denote by
 - $ightharpoonup Y_i(1)$: the outcome unit *i* would attain if they received the treatment
 - \triangleright $Y_i(0)$: the outcome unit *i* would attain if they were part of the control group

Treatment Effects

The **individual treatment effect** for subject *i* can then be written as

$$Y_i(1) - Y_i(0)$$

Unfortunately, in our data we can only observe one of these two potential outcomes.

X_i	$Y_i(0)$	$Y_i(1)$
X_1		$Y_1(1)$
X_2		$Y_{2}(1)$
X_3	$Y_{3}(0)$	
X_n	$Y_n(0)$	

Using the potential outcome notation above, the observed outcome can also be written as

$$Y_i = W_i Y_i(1) + (1 - W_i) Y_i(0)$$

11/36

Average Treatment Effects

- Computing the difference for each individual is impossible.
- ▶ But we will try to use the information we have about the distribution of the data to say something about its average,
- ▶ This is called the **average treatment effect (ATE)** and denoted here by τ :

$$\tau := E[Y_i(1) - Y_i(0)] \tag{2}$$

Average Treatment Effects

- ▶ For this to work we need a couple of assumptions
 - ▶ the data is independently and identically distributed (*iid*)
 - ▶ the potential outcome is independent of the treatment:

$$Y_i(1), Y_i(0) \perp W_i$$

- we are assuming that whether or not a subject received the treatment has nothing to do with how they would respond to this "treatment".
- in other words, treatment assignment is random.

Average Treatment Effect (ATE)

► The independence assumption above allows us to produce a simple estimator for the ATE:

$$\tau = E[\tau_i] = E[Y_i(1) - Y_i(0)] \tag{3}$$

$$= E[Y_i(1)] - E[Y_i(0)] \qquad \therefore \text{ Linearity of expectations}$$
 (4)

$$= E[Y_i(1)|W_i = 1] - E[Y_i(0)|W_i = 0]$$
 : Independence assumption (5)

▶ To know the estimate of the average treatment effect we just need to know the average Y_i for treated and control subjects and compute their difference. The implied estimator is:

$$\hat{\tau} = \frac{1}{n_1} \sum_{i \mid W_i = 1} y_i - \frac{1}{n_0} \sum_{i \mid W_i = 0} y_i \tag{6}$$

where n_1 and n_0 are the numbers of subjects in the treatment and control groups, respectively.

- ► Heterogeneous Treatment Effects: Same treatment may affect different individuals differently
- ► Conditional Average Treatment Effect (CATE)

$$\tau(x) := E[Y_i(1) - Y_i(0)|X_i = x] \tag{7}$$

- ▶ Causal Tree (Athey and Imbens, 2016): A data-driven approach to partition the data into subpopulations that differ in the magnitude of their treatment effects. The approach enables the construction of valid confidence intervals for treatment effects.
- ► Exploring treatment heterogeneity can provide valuable information about how to improve program targeting and what mechanisms drive results.

Sarmiento-Barbieri (Uniandes)

Motivation I: Experiments and Data-Mining

- ► Issues:
 - Ad hoc searches for particularly responsive subgroups may mistake noise for a true treatment effect.
 - Concerns about ex-post "data-mining" or p-hacking
 - preregistered analysis plan can protect against claims of data mining
 - But may also prevent researchers from discovering unanticipated results and developing new hypotheses
- ▶ But how is researcher to predict all forms of heterogeneity in an environment with many covariates?
- ► Athey and Imbens to the rescue
 - ► Allow researcher to specify set of potential covariates
 - Data-driven search for heterogeneity in causal effects with valid standard errors

- ▶ Before proceeding we need to make a couple of assumptions
- ► Assumption 1: Unconfoundedness

$$Y_i(1), Y_i(0) \perp W_i \mid X_i \tag{8}$$

- ► The *unconfoundedness* assumption states that, once we condition on observable characteristics, the treatment assignment is independent to how each person would respond to the treatment.
- i.e., the rule that determines whether or not a person is treated is determined completely by their observable characteristics.
- ► This allows, for example, for experiments where people from different genders get treated with different probabilities,
- ▶ rules out experiments where people self-select into treatment due to some characteristic that is not observed in our data.

► Assumption 2: Overlap

$$\forall x \in \text{supp } (X), \qquad 0 < P(W = 1 \mid X = x) < 1$$
 (9)

- ► The *overlap* assumption states that at every point of the covariate space we can always find treated and control individuals.
- i.e., in order to estimate the treatment effect for a person with particular characteristics $X_i = x$, we need to ensure that we are able to observe treated and untreated people with those same characteristics so that we can compare their outcomes.

Sarmiento-Barbieri (Uniandes)

Causal Trees: Empirical Example (Green and Kern)

- ➤ To illustrate how it works let me use this experiment from the General Social Survey (GSS)
- ▶ GSS conducts surveys regular surveys on Americans think feel about different issues
- ► For decades, scholars studying Americans' support for social welfare spending have noted the special disdain that americans harbor for programs labeled "welfare"
- ▶ This phenomenon became the subject of sustained experimental inquiry in the mid-1980s, when the GSS included a question-wording experiment in its national survey of adults.

Causal Trees: Empirical Example

- Respondents in each survey were randomly assigned to one of two questions about public spending.
- "too much" money is spent on assistance to the Poor (control) or Welfare (treatment)
- ▶ Various explanations put forward: stereotypes associated with welfare recipients and poor people, particularly racial stereotypes, and to political orientations such as individualism and conservatism .
- ▶ Some authors consider the interaction between the treatment and attributions, e.g.
 - ► Federico (2004) examines a complicated three-way interaction between the treatment, education, and racial perceptions.
 - ▶ Jacoby (2000) suggests that party and ideology may make some respondents especially receptive to the more specific program (should strong and weak Democrats be treated as separate subgroups or should they be combined?)

Controls	No	Yes	
Observations	13,198	13,198	
\mathbb{R}^2	0.166	0.215	

- ► We need to proceed in steps
- ▶ Step 1: Split the dataset. Why? → Athey and Imbens innovation
 - ▶ In order to ensure valid estimates of the treatment effect within each subgroup, Athey and Imbens propose a sample-splitting approach that they refer to as honesty:
 - ▶ a method is honest if it uses one subset of the data to estimate the model parameters, and a different subset to produce estimates given these estimated parameters.
 - ▶ In the context of causal trees, honesty implies that the asymptotic properties of treatment effect estimates within leaves are the same as if the tree partition had been exogenously given, and it is one of the assumptions required to produce unbiased and asymptotically normal estimates of the treatment effect.

▶ Divide the data 40%-40%-20% for honest estimation and validation.

```
train_fraction <- 0.80 # Use train_fraction % of the dataset to train our models

df_train <- sample_frac(df, replace=F, size=train_fraction)

df_test <- anti_join(df,df_train, by = "ID") #need to check on larger datasets

split_size <- floor(nrow(df_train) * 0.5)

df_split <- sample_n(df_train, replace=FALSE, size=split_size)

# Make the splits

df_est <- anti_join(df_train,df_split, by ="ID")</pre>
```

► Step 2: Fit the tree

```
fmla_ct <- paste("factor(Y) ~", paste(covariate_names, collapse = " + "))</pre>
ct_unpruned <- honest.causalTree(</pre>
 formula = fmla_ct,  # Define the model
 data = df_split,  # Subset used to create tree structure
 est_data = df_est.
                             # Which data set to use to estimate effects
 treatment = df_split$W,  # Splitting sample treatment variable
 est_treatment = df_est$W,
                             # Estimation sample treatment variable
 split.Rule = "CT",
                             # Define the splitting option
 cv.option = "TOT".
                             # Cross validation options
 cp = 0.
                             # Complexity parameter
 split.Honest = TRUE. # Use honesty when splitting
 cv.Honest = TRUE.
                             # Use honesty when performing cross-validation
 minsize = 25, # Min. number of treatment and control cases in each leaf
 HonestSampleSize = nrow(df_est)) # Num obs used in estimation after building the tree
```

► Step 3: Crossvalidate

```
# Table of cross-validated values by tuning parameter.
ct_cptable <- as.data.frame(ct_unpruned$cptable)</pre>
# Obtain optimal complexity parameter to prune tree.
selected_cp <- which.min(ct_cptable$xerror)</pre>
optim_cp_ct <- ct_cptable[selected_cp, "CP"]</pre>
# Prune the tree at optimal complexity parameter.
ct_pruned <- prune(tree = ct_unpruned, cp = optim_cp_ct)</pre>
ct_pruned

    5) polviews< 3.5 704 115.34030 -0.3167446 *
```

28 / 36

► Step 4: Predict point estimates (on estimation sample)

```
tauhat_ct_est <- predict(ct_pruned, newdata = df_est)
head(tauhat_ct_est)</pre>
```

```
1 2 3 4 5 6
-0.3843850 -0.4283712 -0.3843850 -0.3896395 -0.3896395 -0.3843850
```

29 / 36

- ► Step 5: Compute standard errors
- ► The causalTree package does not compute standard errors by default, but we can compute them using the following trick.
 - ightharpoonup First, define L_l to indicate assignment to leaf l
 - ► Second, consider the following linear model.

$$Y = \sum_{l} L_{l} \alpha_{l} + W L_{l} \beta_{l} \tag{10}$$

► The interaction coefficients in this regression recover the average treatment effects in each leaf, since

$$E[Y|W=1, L=1] - E[Y|W=0, L=1] = (\alpha_1 + \beta_1) - \alpha_1 = \beta_1$$
 (11)

- ► Therefore, the standard error around the coefficients is also the standard error around the treatment effects.
- ▶ We will also use these statistics to test hypothesis about leaf estimates.

```
# Create a factor column 'leaf' indicating leaf assignment
num_leaves <- length(unique(tauhat_ct_est)) #There are as many leaves as there are predictions
df_est$leaf <- factor(tauhat_ct_est, labels = seq(num_leaves))
# Run the regression
ols_ct <- lm(as.formula("Y ~ 0 + leaf + W:leaf"), data= df_est)
ols_ct_summary <- summary(ols_ct)</pre>
```

Table 2: Average treatment effects per leaf

	Estimate	Std. Error
leaf1:W	-0.4611	0.0817
leaf2:W	-0.4284	0.0276
leaf3:W	-0.3896	0.0205
leaf4:W	-0.3844	0.0214
leaf5:W	-0.3758	0.0920
leaf6:W	-0.3315	0.0633
leaf7:W	-0.3167	0.0309
leaf8:W	-0.2124	0.0497

31/36

► Step 6: Predict point estimates (on test set)

```
rpart.plot(
    x = ct_pruned,  # Pruned tree
    type = 3,  # Draw separate split labels for the left and right directions
    fallen = TRUE,  # Position the leaf nodes at the bottom of the graph
    leaf.round = 1,  # Rounding of the corners of the leaf node boxes
    extra = 100,  # Display the percentage of observations in the node
    branch = 0.1,  # Shape of the branch lines
    box.palette = "RdBu") # Palette for coloring the node
```

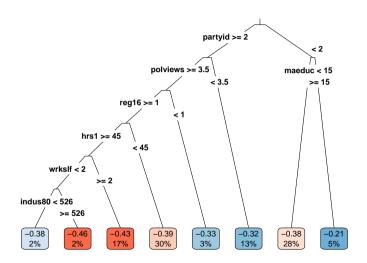

Table 3: Testing null hypothesis: Average treatment effect is same across leaves

	Res.Df	RSS	Df	Sum of Sq	F	Pr(> <i>F</i>)
2	5263	884.921	7	3.4114	2.8984	0.005

34 / 36

Review & Next Steps
